Abstract:
Managing patients with suspected heparin-induced thrombocytopenia (HIT) poses significant clinical challenges. Limited evidence exists on how management decisions impact clinical outcomes, leading to treatment recommendations based on low-certainty evidence. This study aimed to evaluate the treatment strategies and clinical outcomes of patients with suspected heparin-induced thrombocytopenia (HIT) in a contemporary multicenter cohort. We conducted a prospective, multicenter cohort study including consecutive patients with suspected HIT from 11 centers. Patients were stratified into three groups: (a) HIT confirmed, (b) HIT-negative but heparin/PF4 antibody-positive, and (c) HIT-negative without antibodies. Clinical and laboratory data were systematically collected. HIT was diagnosed using the washed-platelet heparin-induced platelet activation (HIPA) test as the reference standard. Among 1,393 patients (46% female, median age 67), HIT was confirmed in 119 (8.5%). Most patients were in intensive care (37%) or had undergone cardiac surgery (32%). Argatroban was the predominant treatment (70%), and platelet recovery occurred in 77% of HIT patients. Among patients with HIT, subsequent venous thromboembolism occurred in 23%, arterial thromboembolism in 9%, major bleeding in 12.6%, and mortality in 18%, with no significant differences between anticoagulants. Treatment with argatroban, bivalirudin, or direct oral anticoagulants (DOACs) significantly reduced arterial thromboembolism risk. Outcomes did not differ between HIT-negative patients with or without heparin/PF4 antibodies. HIT, as well as the mere suspicion of HIT, remains a serious condition with a high risk of adverse outcomes, including death. Our findings provide further evidence supporting the effectiveness of DOACs, argatroban, and bivalirudin in reducing arterial thromboembolism risk.

SUMMARY

Managing patients with suspected heparin-induced thrombocytopenia (HIT) poses significant clinical challenges. Limited evidence exists on how management decisions impact clinical outcomes, leading to treatment recommendations based on low-certainty evidence. This study aimed to evaluate the treatment strategies and clinical outcomes of patients with suspected heparin-induced thrombocytopenia (HIT) in a contemporary multicenter cohort. We conducted a prospective, multicenter cohort study including consecutive patients with suspected HIT from 11 centers. Patients were stratified into three groups: (a) HIT confirmed, (b) HIT-negative but heparin/PF4 antibody-positive, and (c) HIT-negative without antibodies. Clinical and laboratory data were systematically collected. HIT was diagnosed using the washed-platelet heparin-induced platelet activation (HIPA) test as the reference standard. Among 1,393 patients (46% female, median age 67), HIT was confirmed in 119 (8.5%). Most patients were in intensive care (37%) or had undergone cardiac surgery (32%). Argatroban was the predominant treatment (70%), and platelet recovery occurred in 77% of HIT patients. Among patients with HIT, subsequent venous thromboembolism occurred in 23%, arterial thromboembolism in 9%, major bleeding in 12.6%, and mortality in 18%, with no significant differences between anticoagulants. Treatment with argatroban, bivalirudin, or direct oral anticoagulants (DOACs) significantly reduced arterial thromboembolism risk. Outcomes did not differ between HIT-negative patients with or without heparin/PF4 antibodies. HIT, as well as the mere suspicion of HIT, remains a serious condition with a high risk of adverse outcomes, including death. Our findings provide further evidence supporting the effectiveness of DOACs, argatroban, and bivalirudin in reducing arterial thromboembolism risk.

GRAPHICAL ABSTRACT

KEY POINTS:

1. HIT, as well as the mere suspicion of HIT, remains a serious condition with a high risk of adverse outcomes, including death.
2. Further evidence supporting the effectiveness of DOACs, argatroban, and bivalirudin in reducing arterial thromboembolism risk

INTRODUCTION

Despite advancements in diagnostic tests and treatment options, managing patients *with suspected heparin-induced thrombocytopenia (HIT)* remains a major clinical challenge [1–5]. Many hospitalized patients continue to receive unfractionated heparins (UFH) or low-molecular-weight heparins (LMWH), with an estimated 12 million individuals exposed annually in the United States alone [6]. A considerable proportion develop thrombocytopenia, often accompanied by thromboembolism, raising suspicion of HIT [7,8]. In recent years, new clinical scenarios, such as COVID-19 and vaccine-induced immune thrombotic thrombocytopenia (VITT), have emerged, increasing the complexity of HIT diagnosis and management [9–11]. Additionally, the growing use of extracorporeal membrane oxygenation (ECMO) in critically ill patients has further heightened the risk of thrombocytopenia and HIT [12]. In this setting, clinicians face a high-stakes decision—whether to discontinue heparin, which itself carries thromboembolic risks, or to initiate an alternative anticoagulant, increasing the risk of major bleeding [13,14].

Early treatment of suspected HIT aims to prevent serious thromboembolic complications [3,6,15,16]. However, these complications may arise not only from HIT itself but also from the underlying condition requiring heparin. Discontinuing heparin in patients without HIT introduces its own thromboembolic risks, while switching to alternative anticoagulants increases the likelihood of major bleeding [14]. Patients with suspected HIT are particularly vulnerable due to prior cardiopulmonary surgery, thrombocytopenia, glycoprotein IIb/IIIa inhibitor therapy, and frequent postoperative complications [15,17]. Moreover, the benefits of many

treatment decisions remain uncertain, and current guidelines acknowledge that most recommendations are based on low-certainty evidence [6,13].

In the absence of randomized controlled trials, understanding real-world clinical outcomes is essential. Early studies reported high rates of thromboembolism and mortality in HIT patients [16,18]; however, treatment approaches and patient characteristics have evolved significantly. With new diagnostic tools, treatment options, and changing patient populations, there is a need to reassess clinical outcomes [19]. Additionally, many studies on alternative anticoagulants relied on composite endpoints, limiting the ability to assess whether new thromboembolic events could be effectively prevented [13,20,21]. Furthermore, the clinical outcomes of patients *with suspected HIT* who test negative—either by heparin/PF4 immunoassay or functional assays—remain essentially unknown [6]. Data on bleeding risks with non-heparin anticoagulants, particularly in patients without definitive HIT, are also limited [14,20]. Moreover, despite increasing interest in direct oral anticoagulants (DOACs), robust evidence on their efficacy and safety remains scarce [6,12,13].

Many earlier studies have methodological limitations, including retrospective designs with unrepresentative patient selection, small sample sizes, single-center data collection, and inconsistent diagnostic criteria for HIT [14,19,22]. As a result, their findings may not accurately reflect contemporary clinical practice. To address these gaps, several researchers and scientific societies have called for prospective studies that assess patient outcomes using standardized definitions and rigorous data collection methods [6,13,14,19].

To address these knowledge gaps, we conducted a prospective, multicenter cohort study to comprehensively assess the clinical outcomes of patients *with suspected HIT*. Our study aimed to evaluate the risk of thromboembolism, major bleeding, and mortality in confirmed HIT cases, as well as in patients without HIT, stratified by heparin/PF4 antibody status. By applying strict and uniform criteria for HIT diagnosis and ensuring complete and accurate data collection, we sought to generate robust evidence to inform clinical decision-making.

METHODS

Study Design, Setting, and Patient Population

The TORADI-HIT study is a prospective, multicenter cohort study that included 1,393 patients with suspected HIT from 11 centers in Switzerland, Germany, and the United States (Figure 1) [23–26]. Patients were enrolled consecutively between January 2018 and May 2021, but not all study centers were actively recruiting at all time points. Inclusion criteria were: (a) suspected HIT, defined by at least one of the following—heparin/PF4 immunoassay ordered, application of a clinical assessment tool, or hematology consultation requested; (b) age >18 years; and (c) provision of informed consent. Patients were excluded if sample material was missing or if clinical data were insufficient.

Patients were recruited from a well-established study network encompassing university and tertiary hospitals. Depending on the study center, either general informed consent or individual study-specific consent was obtained. Ethical approval was granted by the responsible committees (Kantonale Ethikkommission Bern, #2017-01073), and the study was conducted in accordance with the Declaration of Helsinki.

Data Collection and Study Procedures

A standardized protocol for data collection was developed and approved by the ethics committee. Specially trained study nurses collected clinical and laboratory data and entered them into an electronic case report form (e-CRF) within the REDCap database. The study workflow is outlined in Figure 1.

To ensure high-quality data collection, training sessions were conducted at each study site. Data were retrieved from hospital information systems at two key time points: (1) at the time of HIT suspicion and (2) at hospital discharge. Predefined data collection forms were integrated into routine clinical workflows. Attending physicians were contacted to resolve missing or inconsistent data. In cases requiring further clarification, an expert committee, consisting of the local hematologist and the center hematologist, reviewed the data.

Baseline data included demographic characteristics, clinical setting, laboratory values, and HIT probability scores [23]. Follow-up data at discharge included anticoagulation management (continuation, discontinuation, or switch to an alternative anticoagulant), details of any alternative anticoagulant used, instances of re-exposure to UFH, administration of intravenous immunoglobulin (IVIG), platelet

count at discharge, platelet recovery status (no recovery, < 50% increase, > 50% increase, or more than 100G/L), imaging-confirmed venous and arterial thromboembolism, major and minor bleeding events, mortality, and length of hospital stay. Major bleeding was defined according to the most widely accepted definition of the International Society on Thrombosis and Haemostasis (ISTH): clinically overt bleeding associated with a hemoglobin drop of ≥2 g/dL, transfusion of ≥2 units of red blood cells, bleeding in a critical site, or a fatal outcome [27].

Definition of HIT

Patients were classified as having HIT if they tested positive in the washed-platelet heparin-induced platelet activation (HIPA) test. Washed platelet assays (i.e., HIPA and serotonin release assay, SRA), demonstrated an adequate diagnostic sensitivity and specificity [6,15,28–34]. Clinical studies demonstrated a high agreement with clinical HIT [35,36] and HIPA and SRA are both regarded as reference gold standard for the diagnosis of HIT by the ASH guidelines [6], the British Committee for Standards in Haematology [34], and many authors [6,15,28–30,34,37]. The analytical performance and all methodological details of the in-house HIPA assay were validated in prior studies [31,32].

The HIPA test was performed using washed platelets from four different donors under the following conditions: (a) with buffer, (b) with low-molecular-weight heparin (0.2 IU/mL), and (c) with unfractionated heparin (100 IU/mL). A test was considered positive if platelet aggregation occurred in at least two donors within 30 minutes in the presence of 0.2 IU/mL heparin but not in the presence of 100 IU/mL heparin. Each test plate included both positive and negative controls.

Statistical Analysis

Patients were categorized into three groups: (1) HIT-confirmed, (2) HIT-negative but heparin/PF4 antibody-positive, and (3) HIT-negative without antibodies. Patient characteristics, treatment patterns, and clinical outcomes were summarized using medians with interquartile ranges (IQR) for continuous variables and counts with percentages for categorical variables.

For patients with confirmed HIT, we used multivariable logistic regression to assess risk factors for adverse outcomes, including incomplete platelet recovery, major bleeding, venous thromboembolism, arterial thromboembolism, and mortality. Models were adjusted for sex, age, clinical setting, sepsis, chemotherapy, hemoglobin concentration, white blood cell count, platelet nadir, heparin/PF4 antibody levels, and anticoagulation regimen.

To evaluate differences in outcomes among HIT-negative patients with or without heparin/PF4 antibodies, we conducted additional multivariable logistic regression analyses, adjusting for the same covariates. All statistical tests were two-tailed, and a

p-value <0.05 was considered statistically significant. Analyses were performed using R version 4.3.1.

RESULTS

Baseline Characteristics of Patients with Suspected HIT

A total of 1,393 patients from 11 study centers were included in the analysis. The median age was 67 years, and 46% of patients were female. Most patients were in intensive care units (37%) or had undergone cardiovascular surgery (32%). Other clinical settings included internal medicine (20%), general surgery (10%), and major trauma (1%).

Sepsis was present in 49% of patients, and 7% had a confirmed SARS-CoV-2 infection. Unfractionated heparin was administered to 79% of patients, and low-molecular weight heparin to 43% of patients. The median 4Ts score was 3 (IQR: 2–5). The platelet nadir was lower in patients with confirmed HIT compared to those without HIT (median: 52 $\times 10^9$/L vs. 60 $\times 10^9$/L). Heparin/PF4 immunoassay results and additional patient characteristics are summarized in Table 1.

HIT was confirmed in 119 patients (8.5%) based on the HIPA test. Among HIT-positive patients, 33% were in intensive care and 40% had undergone cardiovascular surgery. The prevalence of heparin/PF4 antibodies was higher in HIT-positive patients than in HIT-negative patients (median CLIA value: 10.35 U/mL vs. 0.00 U/mL). Five patients with HIT (HIPA+) had a CLIA result below 1 U/l. Of these five patients, one also had a negative HIT IgG ELISA result.

Treatment Strategies and Clinical Outcomes

Alternative anticoagulation was initiated in 299 patients (21.5%), with the majority receiving argatroban (56%), followed by fondaparinux (20%) and rivaroxaban (8%). Intravenous immunoglobulin (IVIG) was administered to 5% of patients. Among patients with HIT, 94% received an alternative anticoagulant, whereas 9% of HIT-negative patients were also treated with non-heparin anticoagulants.

Complete platelet recovery was observed in 77% of patients with HIT but was considerably lower in HIT-negative patients (Table 2). Subsequent venous thromboembolism occurred in 23% of HIT-positive patients, while arterial thromboembolism was observed in 9%. Major bleeding was reported in 12.6% of

HIT-positive patients and 12.9% of HIT-negative patients. The overall mortality rate was 18% in HIT-positive patients and 21% in HIT-negative patients.

Notably, any non-heparin anticoagulant use was strongly associated with a lower risk of subsequent arterial thromboembolism but did not significantly affect venous thromboembolism rates. Among treatment strategies, fondaparinux ($p = 0.01$) and argatroban ($p = 0.02$) were associated with an increased risk of major bleeding.

Risk Factors for Adverse Outcomes

We analyzed potential risk factors for major adverse outcomes, including incomplete platelet recovery, subsequent venous and arterial thromboembolism, major bleeding, and mortality in patients with HIT (Table 3). Most patient characteristics were not significantly associated with these outcomes. However, male sex was linked to a higher risk of venous thromboembolism ($p = 0.006$), and intensive care unit admission or major trauma status was marginally associated with major bleeding ($p = 0.05$ and $p = 0.04$, respectively).

Clinical Outcomes in HIT-Negative Patients

We assessed risk factors for adverse outcomes in HIT-negative patients to determine whether the presence of heparin/PF4 antibodies influenced clinical events (Table 4). As expected, established risk factors in hospitalized patients—such as ICU admission, sepsis, low hemoglobin, high white blood cell count, and chemotherapy—were significantly associated with adverse outcomes.

However, heparin/PF4 antibody positivity had no significant impact on thromboembolism, major bleeding, or mortality. These findings suggest that, among HIT-negative patients, antibody presence alone does not influence clinical outcomes.

DISCUSSION

This prospective, multicenter cohort study systematically assessed the clinical outcomes of patients *with suspected HIT*. Of the 1,393 patients included, 8.5% were found to have HIT (prevalence). Regardless of whether the final diagnosis was HIT or not, we observed high rates of subsequent thromboembolic complications, major bleeding and death. In patients *with HIT*, treatment with argatroban, bivalirudin or direct oral anticoagulants (DOACs) was consistently associated with a reduced risk of arterial thromboembolism. However, this was not the case with regard to venous

thromboembolism. Patients without HIT—regardless of heparin/PF4 antibody status—had similar clinical outcomes, suggesting that antibody positivity alone does not confer an increased risk of adverse events.

Several earlier studies reported high thromboembolism and mortality rates in patients with HIT, but their findings were largely based on retrospective data, single-center cohorts, or outdated treatment practices [16,18,38]. Our study confirms that HIT remains a serious condition with substantial risks, but it also reflects contemporary clinical management, including the increasing use of DOACs. Compared to historical cohorts, where thromboembolism rates often exceeded 50%, our findings suggest a possible improvement in patient outcomes, potentially due to more systematic HIT recognition and optimized anticoagulation strategies. We observed a lower rate of complete platelet recovery (77%) than reported in some prior studies [13], which may reflect differences in study design, patient populations, or real-world treatment conditions. While previous research has suggested that heparin/PF4 antibody positivity in HIT-negative patients could indicate an increased thrombotic risk, our data do not support this, adding to the growing uncertainty about the clinical significance of isolated antibody positivity.

A major strength of our study is its large sample size and prospective, multicenter design, which minimizes selection bias and enhances generalizability. By systematically applying the HIPA test as a reference standard for HIT diagnosis, we ensured a uniform classification of cases. Additionally, our structured data collection process, including predefined protocols and expert review of unclear cases, reduced the risk of misclassification and missing data. The inclusion of a large, consecutive patient cohort across different clinical settings further strengthens the applicability of our findings.

However, some limitations must be acknowledged. Despite being one of the largest prospective HIT studies to date, the sample size remains limited for certain subgroup analyses, particularly when comparing different anticoagulants. In addition, we may have missed HIT patients whose treating physician did not express any suspicion. However, we believe that awareness is high in the study centers participating in the TORADI-HIT study and that the risk of missing cases is therefore low. The relatively low prevalence is confirmation of this. We also believe that the key findings of the study would not be influenced by selection bias. As another limitation, three study

centers accounted for the majority of patients (Table 1 of the supplementary material). In such a constellation, distortions in the numerical results are possible in principle. However, we cannot envision how these could have influenced the key findings of the study. Besides, one might argue that despite the high degree of agreement between the two washed platelet tests SRA and HIPA, the good clinical data, and the recommendations of all major professional societies, it cannot be ruled out that SRA detects slightly more cases of HIT. We agree that it would change the numerical results somewhat. However, we cannot imagine how it would change the basic conclusions of the paper. Another finding of our study was that treatment with non-heparin anticoagulants was not associated with major bleeding. However, this contradicts previous studies and may be due to the specific study population at hand being at risk of major bleeding for various other reasons. Finally, our findings may not be fully generalizable to settings where HIT diagnostics or treatment strategies differ systematically from those used in our study centers.

The question arises as to what these results mean for clinical practice, and for medical research. As this was not a randomized clinical trial that directly compared different treatments, nor did it have a large enough sample size in all subgroups, we cannot provide specific recommendations for salient clinical questions. However, it is one of the largest HIT cohorts, probably with the most rigorous methodology, so the results must be considered in the current state of knowledge. Firstly, patients with suspected HIT have a very high risk of complications and death, regardless of whether HIT is actually present. Thrombocytopenia and thromboembolism (presumable driver of suspicion) are manifestations and consequences of a wide variety of serious diseases, especially in critically ill patients. Secondly, non-heparin anticoagulants are consistently associated with a significantly reduced risk of arterial thromboembolism but not with venous thromboembolism. Although we cannot completely rule out spurious results due to the moderate number of cases, we see no statistical indication of them. Therefore, we tend to assume that this is a genuine phenomenon, which could be explained by the lower efficacy of non-heparin anticoagulants on venous thromboembolism, for example. Thirdly, we see no evidence in our cohorts that DOACs are less effective than intravenous anticoagulants, which further supports their use in clinical practice. And fifthly, our data provide no evidence that patients without HIT but with positive H/PF4 antibodies are at higher risk of complications than patients without. This could be

due to the more rigorous study design compared to previous studies and does not support a specific treatment for these patients. As the next step in scientific inquiry, we propose, if possible in this difficult population, to conduct an RCT comparing argatroban, as the most established non-heparin anticoagulant, with rivaroxaban, as the potentially safest and most simple drug.

In conclusion, our data indicate that despite advances in diagnosis and treatment, HIT remains a serious condition with a high risk of complications. Interestingly, the mere suspicion of HIT, presumably arising from thrombocytopenia and thromboembolism, emerges risk factor for serious complications including death. Besides, our findings provide further evidence supporting the effectiveness of non-heparin anticoagulants, including DOACs, in reducing arterial thromboembolism. DOACs are a promising therapeutic option, but further research is needed to refine anticoagulation strategies and ensure both efficacy and safety.

FIGURES

Figure 1: Flow of patients included in the study

Table 1: Baseline characteristics of patients with suspected heparin-induced thrombocytopenia (HIT). This table presents demographic, clinical, and laboratory characteristics of 1,393 consecutive patients included in a prospective multicenter cohort study. Patients were stratified into three groups: (1) HIT-negative without heparin/PF4 antibodies, (2) HIT-negative with heparin/PF4 antibodies, and (3) HIT-positive, defined by a positive washed-platelet heparin-induced platelet activation (HIPA) test. Abbreviations: ab, antibody; ICU, intensive care unit; CRP, C-reactive protein; CLIA, chemiluminescent immunoassay capturing antibodies against heparin/PF4 complexes; IQR, inter-quartile range

	HIT negative		HIT positive	
	H/PF4-ab negative	H/PF4-ab positive	HIPA positive	Missing data
n	1201	73	119	
Male sex - n (%)	765 (63.9)	51 (69.9)	71 (59.7)	
Age - median [IQR]	67.25 [58.05, 75.19]	61.31 [54.23, 75.88]	64.65 [55.50, 74.48]	
Setting -n (%)				1 (0.1)
ICU	443 (36.9)	36 (49.3)	40 (33.6)	
Cardiovascular surgery	376 (31.3)	20 (27.4)	47 (39.5)	
Internal medicine	246 (20.5)	11 (15.1)	16 (13.4)	
General surgery	118 (9.8)	5 (6.8)	9 (7.6)	
Major Trauma	4 (0.3)	0 (0.0)	6 (5.0)	
Other	13 (1.1)	1 (1.4)	1 (0.8)	
Sepsis - n (%)	578 (48.1)	42 (57.5)	57 (47.9)	0 (0.0)
CRP [mg/L] - Median [IQR]	89 [35, 176]	64 [20, 150]	87 [44, 146]	86 (6.2)
SARS-CoV-2 infection - n(%)	67 (5.6)	15 (20.8)	7 (5.9)	9 (0.6)
Unfractionated heparin - n (%)	934 (77.8)	61 (83.6)	103 (86.6)	0 (0.0)
4Ts Score - Median [IQR]	3 [2, 4]	4 [3, 5]	5 [4, 6]	0 (0.0)
Platelet nadir [10^9/L] - Median [IQR]	60 [38, 85]	76 [46, 115]	52 [32, 73]	22 (1.6)
CLIA [U/ml] - Median [IQR]	0.0 [0.00, 0.09]	2.27 [1.48, 4.90]	10.35 [3.76, 24.59]	75 (5.4)

Table 2: Treatment and outcomes of patients with suspected heparin-induced thrombocytopenia (HIT). This table summarizes treatment strategies and clinical outcomes in

patients with suspected HIT (n=1,393). Patients were stratified into three groups: (1) HIT-negative without heparin/PF4 antibodies, (2) HIT-negative with heparin/PF4 antibodies, and (3) HIT-positive, defined by a positive washed-platelet heparin-induced platelet activation (HIPA) test. Results are grouped by final diagnosis, which was not available at the time of initial treatment decisions. Abbreviations: ab, antibody; IVIG, intravenous immunoglobulins; IQR, inter-quartile range.

	HIT negative		HIT positive	
	H/PF4-ab negative	H/PF4-ab positive	HIPA positive	Missing data
Treatment				
IVIG - n (%)	30 (2.6)	0 (0.0)	6 (5.1)	34 (2.4)
Alternative anticoagulant started - n (%)	111 (9.3)	65 (89.0)	112 (94.1)	11 (0.7)
Argatroban - n (%)	43 (3.6)	47 (64.4)	83 (69.7)	
Bivalirudin - n (%)	5 (0.4)	5 (6.8)	12 (10.1)

Edoxaban - n (%)	3 (0.2)	1 (1.4)	1 (0.8)	
Dabigatran - n (%)	0 (0.0)	0 (0.0)	1 (0.8)	
Others - n (%)	2 (0.2)	1 (1.4)	4 (3.4)	
Outcomes				
Platelet recovery - n (%)				53 (3.8)
Not recovered	159 (13.8)	6 (8.5)	7 (6.2)	
Partially recovered	303 (26.2)	25 (35.2)	19 (16.8)	
Fully recovered	694 (60.0)	40 (56.3)	87 (77.0)	
Platelets at follow up [10^9/L] - Median [IQR]	162 [86, 274]	194 [120, 350]	203 [110, 280]	28 (2.0)
Venous thromboembolism - n (%)	66 (5.6)	8 (11.3)	27 (23.1)	30 (2.2)
Arterial thromboembolism - n (%)	55 (4.7)	6 (8.5)	11 (9.4)	30 (2.2)
Major bleeding - n (%)	159 (13.4)	6 (8.2)	15 (12.6)	13 (0.9)
Death - n (%)	260 (21.7)	11 (15.1)	21 (17.6)	1 (0.1)

Table 3: Risk factors for adverse outcomes in patients with confirmed heparin-induced thrombocytopenia (HIT). This table presents multivariable regression models identifying risk factors for major adverse outcomes during the clinical course, including incomplete platelet recovery, venous and arterial thromboembolism, major bleeding, and mortality. Regression coefficients and 95% confidence intervals (CI) are reported (a coefficient of 1 indicates no effect). Treatment with alternative anticoagulants was significantly associated with a lower risk of subsequent arterial thromboembolism.

Characteristic	Not fully recovered platelets				Major bleeding				Venous thromboembolism				Arterial thrombosis				Death
